ABSTRACT
Small satellites become a future trend in communications satellite. In this field, nanosatellites are a very promising class which have many advantages over larger satellite segments, such as simplicity, lower manufacturing expense and the ease of deploying in constellation at Low Earth Orbit. This paper is targeted at study, design and fabrication of a microwave active filter for the receiver front-ends using coupled line filter structure for nanosatellite missions. The whole active filter system is a combination of a microstrip bandpass filter and a preceding two-stage wideband low noise amplifier using FET devices. The low noise amplifier plays as an active element, which provides gain and compensates noise from the filter. The system operates in the frequency range of 2 - 2.4 GHz and has a peaked gain of around 16 dB at 2.36 GHz, which is suitable for nanosatellite communication’s applications at S-band. The simulated and measured results of this active filter configuration are presented.

1. INTRODUCTION
Small satellites have been widely applied in communications satellite in recent years. In this section, nanosatellite is being regarded as a proper choice for satellite communication in developing countries, because of its low fabrication budget, ability of integrating numerous in a single launch vehicle, and the possible of arranging in constellation for in-situ operation. The wet mass of a typical nanosatellite lies between 1 and 10 kg, and its dimensions seldomly exceed 30 cm.

The performance of receiver system for nanosatellite missions is mainly governed by the bandpass filter (BPF) and low noise amplifier (LNA) units. Therefore, designing good filtering and low noise amplifying modules are prime requirements of a success communication mission.

In the filter region, there are four major parameters govern the dissipation loss level of a bandpass filter: The filter type, the order of the filter, the unloaded Q-factor of the filter elements and the bandwidth. Universally, all passive bandpass filtering structures encounter a problem of compromising between insertion loss and bandwidth, especially at radiofrequency. For details, the product of these two parameters is a constant [1], a narrower bandpass filter means higher degree of insertion loss. Furthermore, in microwave frequencies, it is really a challenge to construct a high-performance filter with passive elements only, because of the detrimental effects of the parasitic elements. Electronics researchers have taken much efforts to deal with these problems for decades, and thanks to the development of the semiconductor technology, a very promising solution for this limitation is established: Using field effect transistors (FET) as active elements to compensate the insertion loss while maintaining the bandwidth quality of the filter. The system consists of the microwave filter and the active element, which is the LNA in our case, is called Microwave Active Filter (MAF). Fig.1 shows the block diagram of a receiver system including the MAF unit:

In the above figure, the receiving signals first go through a bandpass filter, which lies outside the MAF unit, for a primary filtering process. This filter is necessary because the raw receiving signal is very noisy and contains some amplitude perturbation superimposing components, which can lead to an overload in the LNA. After being filtered, the signals enter the MAF unit and being amplified to a desired amplitude level by the LNA, then go through the BPF of the MAF for a smooth filtering process. Subsequently, at the input of the mixer of the IF stage, we have low noise, well-amplified signals at the desired RF band.

There are previous works related to MAF. An active 8-path filter with a preceding LNA for software-defined radio (SDR) transceivers, in which the center frequency can be tuned from 100 MHz to 2 GHz is presented by Behmanesh and Atarodi [2]. A structure includes an LNA and a bandpass filter called as the Selective RF Low Noise Amplifier, which can be used in FM broadcast band (88 – 108 MHz), is introduced by Lee and Lu [3]. However, these mentioned works used lumped filter elements and can only be properly applied for the frequency range of below 2GHz, these design principles cannot be directly used in the frequency range of 2 GHz and above when taking the dissipation loss and parasitic effects into account. In their electronics letter, Chang and Itoh [4] published a narrowband MAF using microstrip distributed elements, based on the coupled negative resistance method. Though this topology can operate in a frequency range up to 15.5 GHz, it is fairly difficult to put this configuration into application of a high order microstrip filter because of its complexity.

Our designing purpose is to obtain the best trade-off between operation frequency, total efficiency of the system, and simplicity. The key features of the proposed MAF are listed below:
- Has a relative high gain and low noise figure.
- Provides least distortion to the frequency response.
- Has the ability of tuning frequency in a wide range.
- Compact enough to be integrated to the receiver system in either space segment (nanosatellites) or earth segment (small ground stations).

2. DESIGN AND SIMULATION OF THE COUPLED LINE BANDPASS FILTER

The microstrip coupled line bandpass filter is widely used in radiofrequency, because of its equilibrium between performance, simplicity and manufacturing expenses. Similar to a single microstrip line, a coupled microstrip line is a quasi-TEM mode system with no cut-off frequency. For microwave frequency, the filtering topology using microstrip distributed elements have many benefits over the lumped elements topology, such as reduces the parasitic effects, easier to produce, and offers much smaller area and profile.

In the microstrip coupled lines, there are two different modes of field distribution, namely the odd-mode and even-mode, which can be physically explained by the positions of the relative polarities of voltages along the transmission lines. Consequently, it leads to the two characteristic impedances called the odd-mode characteristic impedance ($Z_{od}$) and even-mode characteristic impedance ($Z_{oe}$), which are the two primary parameters in the design procedure [5]. Fig.2 demonstrates the field distribution of these two modes:

![Field distribution over odd and even modes of the coupled lines](image)

Figure 2. The field distribution over odd and even modes of the coupled lines [5]
A half-wavelength parallel coupled line microstrip bandpass filter is a structure included coupled lines which are paralleled in pairs along half of their lengths. Once appropriately spacing the resonator elements, we have a good coupling, thus providing the desired bandwidth. The spacing parameters (or gaps) are denoted by $S$. Along with the gap, there are other governing parameters, namely length ($l$), width ($W$) and characteristic admittance ($Y_0$), which is just the inverse of the characteristic impedance, $Z_0$, of the connecting line. The filter structure is demonstrated in Fig.3:

![Figure 3. The structure of the microstrip parallel coupled line bandpass filter (redrawn from [6])](image)

The following equations are used to design the filter:

$$ J_0 Z_0 = \sqrt{\frac{\pi \cdot \text{FBW}}{2g_0 g_1}} \quad (1) $$

$$ J_{j,j+1} Z_0 = \sqrt{\frac{\pi \cdot \text{FBW}}{2g_j g_{j+1}}} \quad \text{for } j=1 \text{ to } n-1 \quad (2) $$

$$ J_{n,n+1} Z_0 = \sqrt{\frac{\pi \cdot \text{FBW}}{2g_{n-1} g_{n+1}}} \quad (3) $$

Where $g_0, g_1, \ldots, g_n$ are element values, in our case: $g_0 = g_1 = 1$, $g_2 = 1.5963$, $g_3 = 1.0967$. FBW is the filter’s fractional bandwidth. $Z_0$ is the characteristic impedance of the line, as explained before and $J$ (with subscribes) is the characteristic admittances of the inverters. Based on the above equations, we can calculate the characteristic impedances of the odd and even modes of the parallel coupled line microstrip bandpass filter as follows:

$$ (Z_{0.o})_{j,j+1} = Z_0 (1 - J_{j,j+1} Z_0 + (J_{j,j+1} Z_0)^2) \quad (4) $$

$$ (Z_{0.e})_{j,j+1} = Z_0 (1 + J_{j,j+1} Z_0 + (J_{j,j+1} Z_0)^2) \quad (5) $$

In this design, we chose the 3rd order filter with 2 pairs of symmetric filter elements. The calculated values (in Ohms) of the characteristic impedances are shown in Table 1:

<table>

The material used for the filter structure is Rogers FR4, which has the following characteristics: Relative dielectric constant: 4.34, loss tangent: 0.0025, dielectric height: 1.6 mm, conductor thickness: 0.035 mm, roughness: 0.0095. The simulated results in Decibel of the input reflection coefficient ($S_{11}$) and insertion loss ($S_{21}$) have been done by the Advanced Design System (ADS) 2014, provided by Agilent. The schematic design and simulated results are illustrated in Fig.4 and Fig.5, respectively.
As can be seen in Fig.5, the insertion loss ($S_{21}$) and return loss ($S_{11}$) is around 0.95 dB and 21.6 dB at 2.25 GHz, respectively. Furthermore, the ripple in the whole passband is roughly 0.7 dB and the 3-dB bandwidth is approximately 250 MHz.

3. DESIGN AND SIMULATION OF THE WIDEBAND LOW NOISE AMPLIFIER

The low noise amplifier plays a vital role in satellite’s receiver, its main function is to amplify the weak received signal which goes through the satellite’s antenna terminal. In most cases, the LNA should be placed as close as possible to the output of the receiving antenna to minimize the distant loss and thermal noise caused by the connecting cables. From another point of view, the LNA can also act as an active element of a filtering system when positioning it prior to a filter. This leads to some considerable benefits to the signal such as noise compensating, gain boosting and the ability of tuning the peaked gain for frequency selection.

The figures of merit of a typical LNA are gain and signal-to-noise ratio (SNR). In our case, an additional requirement is to maintain an acceptable gain in the frequency range of 2-2.45 GHz. In order to obtain the best compromise between the three above demands, a two-stage LNA configuration is being considered, in which, the first stage is to optimize the signal’s bandwidth as well as noise figure and the second stage is to rise the overall gain. The transistor type used in this LNA topology is SPF-2086, which is fabricated pHEMT GaAs FET technology with high gain, low noise figure and has an operating frequency from 0.1 GHz up to 12 GHz. Fig.6 shows the block diagram of the desired 2-stage LNA:
The LNA network can only work efficiently once being impedance matched properly in both of its input and output. The purpose of impedance matching is to maximize the transferred power from the source to the load and minimize the reflected power from the load to the source, thus optimize the voltage standing wave ratio (VSWR). The figure below demonstrates a typical matching system, which includes input and output matching networks for a single stage of our LNA:

Figure 7. The diagram of impedance matching networks of the single stage of the LNA

In Fig.7, $Z_S$ needs to be matched with $Z_L$, and these parameters both equal 50 Ohms, which is the characteristics impedance ($Z_0$) of the transmission lines. In order to reach this, the values of the reflection coefficients of the input and output matching networks, namely $\Gamma_S$ and $\Gamma_L$, need to be equalized to the corresponding reflection coefficients of the input and output, $\Gamma_{IN}$ and $\Gamma_{OUT}$, of the LNA.

The proposed LNA has the same structure as shown in Fig.8, with the desired bandwidth of 400 MHz and the operation center frequency of 2.3 GHz. The figure below is the schematic diagram of the 2-stage wideband LNA, using the same FR4 substrate as that of the previous coupled line BPF.

Figure 8. Schematic diagram of the 2-stage cascaded LNA

As can be seen in the above figure, the two stages are identical to each other. A 10 pF capacitor has been placed between the two stages in order to reduce the parasitic effect. The impedance matching technique used here is the combination of general and quarter-wave transmission lines. The quarterwave transformers are TL3, TL4, TL15 and TL16, respectively. The center frequencies of both stages are 2.3 GHz. The typical power supply of the SPF-2086 transistors are 5 V/50 mA and the biasing point is reached at -0.5 V. Fig.9 displays the simulated gain and input reflection coefficient of the 2-stage LNA.
It is clearly seen that in Fig. 9, the overall gain ($S_{21}$) is greater than 35 dB at the frequency range of 2.15 – 2.58 GHz, the maximum gain of 38.57 dB is obtained at 2.51 GHz. The input reflection coefficient, $S_{11}$, is approximately -9.6 dB at the desired frequency, which lies in the tolerance range.

4. MEASURED RESULTS

The whole MAF circuit was successfully designed and fabricated in our laboratory based on the ADS package and the LPKF Promomat C40 machine. The testing results of the filter without connecting to the LNA are measured on the Vector Network Analyzer 37369D - Anritsu technology with the linearity range up to 40 GHz. The following figures show the experimental results of the coupled line microstrip bandpass filter without LNA.
As can be seen in the above figures, the experimental results are well matched to the simulated results showed in Fig.5, the insertion loss peaked at around 2.25 GHz. The degrade of the S21 of the fabricated filter in Fig. 10 is caused by cables and connectors’ loss, this value is approximately 2.3 dB. Fig.12 shows the measured result of the MAF system, with the measured frequency ranged from 1.9 GHz to 2.5 GHz. The measure was done by picking the amplitude values of the receiving signal over the measured frequency range with the frequency step of 2.5 MHz, corresponds to 240 points over the whole frequency span.

![Figure 12. The measured S21 of the whole Microwave Active Filter](image)

In Fig.12, the operation frequency range is between 2 and 2.4 GHz, which corresponds to a bandwidth of 400 MHz. The highest gain value is 16.1 dB at around 2.36 GHz and the gain values around the center frequency of the bandpass filter are approximately 14 dB. The actual peaked gain without respect to the cables and connector attenuations is about 20 dB. The fluctuation of the gain range is roundly 5 dB, however, it can be compensated by the S-band receiver’s automatic gain control (AGC). A noticeable trait of the above gain diagram is that the values fall rapidly outside the desired range, for details, from 10 dB at 1.98 GHz to -20 dB at 1.95 GHz and from 10 dB at 2.43 GHz to -20 dB at 2.45 GHz. This is a valuable characteristic of our MAF. However, the most important point, which is also the main goal of our design is that the MAF has the ability of allowing flexibly frequency tuning over the operation band. For example, for a 1-dB ripple passband device, we have at least 3 isolated frequency regions at 2.03 GHz, 2.09 GHz and 2.37 GHz. The frequency slots can be further increased when combining the MAF with a phase-locked loop (PLL) unit in order to do the stepped tuning. It provides undeniable advantages to the multi-frequency satellite communication. For instance, in the frequency span of 300 MHz, we can hop the frequency between 10 slots, width a spectrum bandwidth of around 30 MHz for each slot.

5. CONCLUSION

This paper introduced about a microwave active filter consists of a coupled line microstrip bandpass filter and a wideband low noise amplifier. The simulated and measured results are being presented and it proved good agreement between simulation and practice. The MAF is successfully designed and operated at S-band, and it can be applied to nanosatellite’s receiver front-end at both space and ground segments. The operation range of the proposed MAF is 2-2.4 GHz and the highest gain value is around 20 dB. The MAF allows good stepped frequency tuning at S-band and it proves considerable benefits in comparison to general passive filter systems, such as: Provides considerable high gain signal at the operating band, better frequency response and noise compensating for the filter, and still compact enough to integrate to the nanosatellite’s receivers. Based on the requirement of the communication satellite missions, the flatness and frequency response of the operation band can be further improved when increasing the order of the filter, this can be used for applications that required smooth frequency tuning.
